Inducing Probabilistic Context-Free Grammars for the Sequencing of Robot Movement Primitives

Rudolf Lioutikov\textsuperscript{1}, Guilherme Maeda\textsuperscript{2}, Filipe Veiga\textsuperscript{1}, Kristian Kersting\textsuperscript{3} and Jan Peters\textsuperscript{1,4}

Abstract—Movement Primitives are a well studied and widely applied concept in modern robotics. Composing primitives out of an existing library, however, has shown to be a challenging problem. We propose the use of probabilistic context-free grammars to sequence a series of primitives to generate complex robot policies from a given library of primitives. The rule-based nature of formal grammars allows an intuitive encoding of hierarchically and recursively structured tasks. This hierarchical concept strongly connects with the way robot policies can be learned, organized, and re-used. However, the induction of context-free grammars has proven to be a complicated and yet unsolved challenge. In this work, we exploit the physical nature of robot movement primitives to restrict and efficiently search the grammar space. The grammar is learned with Markov Chain Monte Carlo optimization over the posteriors of the grammars given the observations. Restrictions over operators connecting the search define the corresponding proposal distributions and, therefore, guide the optimization additionally. In experiments, we validate our method on a redundant 7 degree-of-freedom lightweight robotic arm on tasks that require the generation of complex sequences of motions out of simple primitives.

I. INTRODUCTION

Movement primitives (MPs) are a well established concept in robotics. MPs are used to represent atomic, elementary movements and are, therefore, appropriate for tasks consisting of a single stroke-based or rhythmic movement\cite{1}. They have been used in a large variety of applications, e.g., table tennis\cite{2}, pancake flipping\cite{3} and hockey\cite{1}. For more complex tasks, however, a single MP is often not sufficient. Therefore, complex scenarios require sequences of MPs for feasible solutions.

Considering a set or library of MPs, such sequences can be generated in a variety of ways, including Hidden Markov Models\cite{4}, Mixture Models\cite{5} and other hierarchical approaches\cite{6}. Regarding these approaches as mechanism producing sequences of MPs reveals a common, important downside: understanding these mechanisms requires a significant amount of expert knowledge. However, a declared goal of robotics is the deployment of robots into scenarios where a direct or indirect interaction with non-expert users is required. Therefore, more intuitive sequencing mechanisms for non-experts are necessary.

This work proposes the use of formal grammars for the sequencing of MPs. In particular, we focus our attention on probabilistic context free grammars (PCFGs) and propose a method to induce PCFGs from observed sampled sequences of primitives. Formal grammars represent a formal description of symbols and rules, representing the structure of a corresponding language. They have been intensively studied in both natural language processing and compiler construction but have also been applied in a variety of fields, e.g., molecular biology\cite{7}, bioinformatics\cite{8}, computer vision\cite{9} and robotics\cite{10},\cite{11}. PCFGs allow the implicit embedding of hierarchies within the rules of the grammar associating every produced sequence with at least one corresponding parse tree. Such a parse tree represents the derivation of the produced sequence in an intuitive way. Figure\ref{fig:1} shows a learned grammar for placing a stone in a game of tic tac toe, including a parse tree for a produced primitive sequence.

However, the understandability of the grammar itself depends on the size of both the grammar, i.e., the number of possible productions, as well as the length of each possible production. The induction of concise but expressive grammars is considered a non-trivial and in the context of natural language even an ill-posed problem. A common approach to grammar induction is to formulate the problem as a search problem where each possible grammar is a node in the search space and a set of operators generate the edges between those nodes. This search space can than be traversed through different search methods where a scoring function determines

Fig. 1: The robot executes a turn in the tic tac toe game. The turn is represented as a sequence of movement primitives. The sequence was generated by a probabilistic context free grammar, learned from previously labeled observations.
the quality of each grammar. Stolcke et al. [12] suggested to formulate the problem as a Maximum-a-posteriori estimation where the scoring is defined as the posterior given the observations. In order to reduce the possibility of getting stuck in bad local optima the search space was traversed via beam search, but this method is still prone to finding local solutions. We propose scoring using a posterior over the grammar given the observations, however, the search is formulated as a Markov Chain Monte Carlo (MCMC) optimization similarly to [13].

This paper exploits the structure inherently presented in the physical motions to ease the learning of grammars. We assume each segment of the observed sequences to be a sample from an underlying library of movement primitives (e.g. [5], [14]). Due to the considerably small size of a primitive library compared to the corpus of a natural language, the observed sequences of even complex tasks show a simpler structure than a natural language sentence. Furthermore, the type of a movement primitive, e.g., hand movement, arm movement can be easier deduced than the type of a word, e.g., verb, noun. In general, the different types of primitives can be determined automatically by identifying its principal components.

An important restriction, improving the induction of grammars for movements is that any produced sequence has to result in a continuous trajectory inside the state space. Therefore, any grammar that would produce a jump in the state space is invalid and has to be removed from consideration. In this work we avoid such grammars directly by restricting the operators to only produce valid grammars.

The contributions of this work are the induction of Probabilistic Context Free Grammars for the sequencing of movement primitives. The posteriors are computed using a novel prior distribution that not only takes advantages of the physical constraints presented in the domain of movements, but also avoid the many pitfalls of existing methods based on minimum description length and Dirichlet distributions (refer to Section II). The search is formulated as a Markov Chain Monte Carlo optimization where the proposed distributions are defined through restrictions put upon the operators connecting the grammar search space. Differently from methods based on greedy beam search (e.g. [12]), MCMC is a global optimizer.

Another approach featuring a sequence graph was presented in [17]. The graph is learned from demonstrations through an agglomerative clustering scheme. In [18] a hierarchical version of the Relative Entropy Policy Search algorithm [19] is introduced, capable of learning gating-policies to sequence DMPs. In this work, we propose probabilistic context-free grammars as a means of sequencing movement primitives. However, grammars bring the advantage of being a general method capable of representing hierarchies in a principled and intuitive manner.

Motion grammars [10] are extensions of context free grammars modeling the discrete and continuous dynamics of hybrid systems. However the grammars introduced in [10] are predefined and aim at fast task verification. In [11] a probabilistic context free grammar is used to sequence discrete actions. Analogously to [12] the grammar is learned by applying a beam search for the maximal posterior inside the grammar space. The grammar space is traversed by applying the merge and chunk operators [12] of observed sequences (these operators will be defined in detail in Section III). In contrast to [12] a n-gram like frequency table is used to determine reoccurring patterns in the observations, hence, identifying candidate productions for the chunk operator. To avoid unintuitively compact grammars the prior definition, originally defined solely by the minimal description length, was extended by a log-Poisson term similar to [20].

While sharing the motivation of learning intuitive, probabilistic context free grammars for primitive sequencing, our work differs in several ways from [11]. In this work, we use a stochastic movement primitive representation and actively take advantage of its properties to induce the grammar. Here, we deviate from the common structure prior definition as an exponential distribution over the minimal description length and define the entire prior as a combination of several Poisson distributions. Furthermore, we use an Markov chain Monte Carlo optimization to find the grammar maximizing the posterior, similarly to [13], which is more robust to local optima than a beam-search.

The grammar induction approach described in [13] uses the Metropolis-Hastings algorithm [21] to learn grammars describing design in various domains, such as websites and geometric models. They do not use the grammar learning in any robotics context. Moreover, they define the prior using the description length. Our proposed approach differs significantly in the structure of the observed sequences. In [13], the observations and, hence, the starting points of the grammar induction are already hierarchical structures. Therefore, it is sufficient to traverse the grammar space using solely the merge and split operators. These operators allow the generalization and specialization of grammars, but are not able to introduce new hierarchies like the chunk operator [12]. In this work, we apply all three operators. To achieve the required irrediscibility of the Markov chain we additionally introduce the insert operator, negating the effects of the chunk operator. The meaning of the operators shall become clear in the next section.

II. RELATED WORK

Movement primitives are usually used to solve tasks consisting of single, atomic stroke-based or periodic movements [1]. For more complex tasks, however, a sequence of primitives has to be applied. An example of such a complex task is the grasping, positioning, and cutting of a vegetable [15] with Dynamical Movement Primitives (DMPs) [16]. However, in that work the sequences were not learned, but predefined. An approach combining the segmentation of observations and the learning of a sequencing mechanism is presented in [4]. The primitives are encoded using Hidden Markov Models and a graph structure is learned during the segmentation. This graph can be used subsequently to sequence the primitives.

While sharing the motivation of learning intuitive, probabilistic context free grammars for primitive sequencing, our work differs in several ways from [11]. In this work, we use a stochastic movement primitive representation and actively take advantage of its properties to induce the grammar. Here, we deviate from the common structure prior definition as an exponential distribution over the minimal description length and define the entire prior as a combination of several Poisson distributions. Furthermore, we use an Markov chain Monte Carlo optimization to find the grammar maximizing the posterior, similarly to [13], which is more robust to local optima than a beam-search.

The grammar induction approach described in [13] uses the Metropolis-Hastings algorithm [21] to learn grammars describing design in various domains, such as websites and geometric models. They do not use the grammar learning in any robotics context. Moreover, they define the prior using the description length. Our proposed approach differs significantly in the structure of the observed sequences. In [13], the observations and, hence, the starting points of the grammar induction are already hierarchical structures. Therefore, it is sufficient to traverse the grammar space using solely the merge and split operators. These operators allow the generalization and specialization of grammars, but are not able to introduce new hierarchies like the chunk operator [12]. In this work, we apply all three operators. To achieve the required irrediscibility of the Markov chain we additionally introduce the insert operator, negating the effects of the chunk operator. The meaning of the operators shall become clear in the next section.
III. BACKGROUND

Before showing how to induce the probabilistic language of movements, this section briefly presents the principal concepts of probabilistic context free grammars (PCFGs). A PCFG is a 4-tuple $G = (A, V, R, S)$, consisting of a set of terminals $A = \{a_1, a_2, a_3, \ldots, a_{|A|}\}$, a set of nonterminals $V = \{A_1, A_2, A_3, \ldots, A_{|V|}\}$, a set of starting symbols $S \subseteq V$, and a set of production rules $R = \{(A, R_A, \rho_A) | A \in V\}$. The ordered set $R_A \in ((A \cup V)^{*})^{R_A|A|}$ is referred to as the productions of the nonterminal $A \in V$ and the elements $\rho \in \rho_A$ of the multinomial $\rho_A \in \Delta^{R_A|A|-1}$ are the probabilities or parameters of $A$. A common example grammar is the one describing the language $a^n b^n$

$$G = (A, V, R, S),$$
$$A = \{a, b\}, \ V = \{A\}, \ S = \{A\},$$
$$R = \{(A \rightarrow ab, \rho_{A} | 0.7, 0.3^{T})\}.$$

This grammar describes the language of all sequences that consist of any number of $as$ followed by the same number of $bs$. An alternative, more common but less formal notation for the rule set is

$$R = \{A \rightarrow ab \quad [0.7],$$
$$A \rightarrow aAb \quad [0.3]\},$$

which illustrates, the function of a rule. The nonterminal on the left hand side, $A$, can produce the sequences $ab$ and $aAb$ on the right hand side with a probability of 0.7 and 0.3 respectively.

Learning formal grammars from sequences of terminals is referred to as grammar induction. Commonly the task is formulated as a search through a grammar space $S$, where the connections between grammars are represented as different operators. Such operators manipulate the set of production rules $R$ and the set of nonterminals $V$ accordingly. Starting from an initial grammar $G^0$ these operators are used to traverse the grammar space, searching for the optimal grammar $G^*$. Various search strategies have been suggested, e.g. beam search [12], [11] and Markov chain Monte Carlo optimization [13].

IV. INDUCING A PCFG FOR MOVEMENT PRIMITIVES

Given a set of primitives $\Theta = \{\theta_1, \theta_2, \theta_3, \ldots, \theta_{|\Theta|}\}$ and a set of labeled demonstrations $D = \{d_1, d_2, d_3, \ldots, d_{|D|} | d_i \in \Theta^+\}$, the goal is to learn the PCFG $G^*$ that maximizes the posterior

$$G^* = \arg \max_p (G|D). \quad (1)$$

In this work, we define the set of terminals as the set of primitives $A = \Theta$. During the learning of the grammar the terminals, and, hence the primitives are considered immutable, implying that the search space consists of grammars that only differ in $S$, $V$ or $R$. Each grammar represents a node in the grammar space $S$, while the directed edges between nodes are defined by operators. Operators manipulate the rule set $R$ of a grammar $G$ and consequently create a new grammar $G'$. The grammar space $\Phi$ is illustrated in Figure 2. In this work we apply four different operators spanning $\Phi$, that are described in more detail below. Furthermore, a Markov chain Monte Carlo optimization is used to find the grammar $G$ that maximizes the posterior $p(G|D)$.

A. Learning grammars through posterior optimization

The posterior $p(G|D)$ describes how probable a given grammar $G$ is given the observed sequences $D$. By applying Bayes theorem we can reformulate the posterior, and, hence the maximization as

$$G^* = \arg \max_p (G|D), \quad (2)$$
$$G^* = \arg \max_p (D|G) \cdot (G), \quad (3)$$

where $p(D|G)$ is the likelihood of the labeled demonstrations $D$ given the grammar $G$, as presented in Section [IV-A].

In Section [IV-A.] we discuss common choices for the prior $p(G)$. We finally introduce a novel grammar prior based on Poisson distributions in Section [IV-A.]

1) The likelihood $p(D|G)$ is computed for each demonstration independently, yielding

$$p(D|G) = \prod_{d \in D} p(d|G). \quad (4)$$

Depending on the grammar $G$ the sequence $d$ could have been produced in multiple ways. Considering every possible derivation results in the sum-product formulation

$$p(d|G) = \frac{1}{\text{parse}(d,G)} \sum_{\tau \in \text{parse}(d,G)} \prod_{(A,r,\rho) \in \tau} \rho,$$

where $\tau$ represents a single parse tree and $\text{parse}(d,G)$ denotes a function producing all feasible parse trees. The 3-tuple $(A,r,\rho)$ represents an edge in the parse tree $\tau$ connecting the nonterminal $A$ and its production $r \in R_A$ with a probability of $\rho \in \rho_A$. In this work the function $\text{parse}$ creating all possible parse trees for a given demonstration $d$ is implemented by the Earley parser [22]. While the Earley parser suffers from a higher complexity compared to other
The key to achieving this goal is the grammar structure, of significance for the overall grammar prior amplified with an exponential weighting term \[13\] to remain extended with the log of a Poisson distribution with mean \(\eta\) be intuitive for non-experts. In order to prefer grammars such a prior can lead to grammars that are too compact to MDL (\[23\]), yielding the over all description length.

The dependency on the grammar structure is implicit, since the probabilities \(p_A \in \rho_G\) depend on both the set of nonterminals \(V\) and the productions for each nonterminal \(R_A\). The parameters for each nonterminal \(p_A \in \rho_G\) form a multinomial distribution, i.e., \(\sum_{\rho \in \rho_A} \rho = 1\). Therefore, a Dirichlet distribution would be an obvious choice for the probability distribution over the parameters \(p(p_A)\) for a single nonterminal \(A \in V\). A significant drawback of using a Dirichlet distribution is its factorial growth in the dimensionality of the multinomial. In fact using an uninformative Dirichlet distribution, i.e., setting the concentration parameters to 1.0 will result in a probability density of \(p(p_A) = (\text{dim}(\rho_A) - 1)!\) for any \(\rho_A \in \rho_G\).

To compensate for this growth the structure prior \(p(G_R)\) is usually modeled as an exponential distribution over the minimal description length (MDL) of the grammar structure \(G_R\). Every symbol in the production rules, terminal and nonterminal, contribute to the MDL with \(\log_2(|A| + |V|)\) bits, yielding the over all description length

\[
\text{MDL}(G_R) = \sum_{(A,R_A) \in G_R} \sum_{r \in R_A} \text{MDL}(r),
\]

\[
\text{MDL}(r) = (1 + |r|) \log_2(|A| + |V|).
\]

A prior \(p(G_R)\) defined as an exponential distribution over the MDL \(G\) will prefer small and concise grammars. However, such a prior can lead to grammars that are too compact to be intuitive for non-experts. In order to prefer grammars with a desired production length, \(\eta_r\), the MDL has been extended with the log of a Poisson distribution with mean \(\eta_r\) [20], [11]. Because of the factorial growth of the parameter prior \(p(p_G|G_R)\) the structure prior is often additionally amplified with an exponential weighting term \[13\] to remain of significance for the overall grammar prior \(p(G)\) and, hence, the posterior \(p(G|D)\).

The likelihood \(p(D|G)\) is defined as a product over the average of probabilities, which always results in \(p(D|G) \leq 1\). However, the described grammar prior \(p(G)\) is the product of two probability densities, which will very quickly result in \(p(G) \gg 1\) and therefore dominate the posterior.

3) The novel prior: presented in this paper aims at inducing PCFGs, which are easily understandable for non experts. The key to achieving this goal is the grammar structure, rather than the grammar parameters. Therefore, we suggest a grammar prior, that does not explicitly model a Dirichlet distribution over the parameters but instead implicitly considers the parameters in the overall grammar prior \(p(G)\). We therefore, model the parameter prior and the structure prior jointly \(p(G) = p(\rho_G, G_R)\)

\[
p(\rho_G, G_R) = \frac{p(|R|\eta_R)}{|R|} \sum_{(A,R_A,\rho_A) \in R} \gamma(A, R_A, \rho_A)
\]

\[
\gamma(A, R_A, \rho_A) = p(|R|\eta_R)p(R_A|\rho_A, \eta_r),
\]

where the probabilities over the number of rules \(p(|R|\eta_R)\) and the size of each rule \(p(|R|\eta_R)\) are modeled as Poisson distributions with means \(\eta_R\) and \(\eta_r\). The probability of each rule is modeled as a weighted average

\[
p(R_A|\rho_A, \eta_r) = \sum_{r \in R_A} \rho(p(r)\eta_r),
\]

over the probabilities of the corresponding productions. The weighting is given by the grammar parameters \(\rho \in \rho_A\) and the probability of each production corresponds to the Poisson distribution over its length \(p(|r|\eta_r)\), given a desired production length \(\eta_r\). Since all components are defined as discrete probabilities, the prior is always \(p(G) \leq 1\), eliminating the need for hard to tune weighting terms to cope with difficult scaling properties. Furthermore, the prior \(p(G)\) will now prefer grammars with \(\eta_R\) productions per nonterminal with an average length of \(\eta_r\) symbols per production. The hyper-parameters \(\eta_R, \eta_r\) can be set to achieve a desired simplicity of the grammar. By weighting each production \(r \in R_A\) with the corresponding grammar parameter \(\rho \in \rho_A\) the prior gives more significance to production which are more likely to occur.

B. Traversing the grammar space \(\mathcal{G}\)

To find the optimal grammar \(G^*\), it is necessary to define mechanisms that generate new grammars. A common choice is to define operators \(op \in \mathcal{O}\), where \(\mathcal{O}\) denotes the set of all operators. Each operator \(op\) manipulates the rule set \(R\) and consequently the nonterminal set \(V\) of a given grammar \(G\), therefore, creating a new grammar \(G'\). For each operator \(op\) we define a domain \(\Omega_{op}\) that \(op\) can act upon. The elements in \(\Omega_{op}\) depend on the operator itself and can be for instance nonterminals, pairs of nonterminals or productions.

Each grammar represents a node in a grammar space \(\mathcal{G}\). The operators \(op \in \mathcal{O}\) represent directed edges in \(\mathcal{G}\) between two grammars. The grammar space \(\mathcal{G}\) is illustrated in Figure 2. After a grammar \(G'\) was created by applying an operator \(op\) on grammar \(G\), the grammar parameters usually have to be re-computed. In this work, the parameters are re-estimated for every new grammar \(G'\) via the Inside-Outside algorithm [23].

Not every possible grammar \(G\) is suitable for sequencing movement primitives. Every sequence produced by \(G\) has to guarantee a smooth, continuous trajectory within the state space of the MPs. In general, this means that precedent
primitives should finish somewhat closer to the beginning of the next primitive.

We restrict the grammar space $\mathcal{G}$ to only contain grammars that fulfill this continuity requirement. The restriction is achieved by limiting the domain $\Omega_{\text{op}}$ of each operator $\text{op} \in \mathcal{O}$, such that if grammar $\mathcal{G}$ fulfills the continuity requirement any grammar $\mathcal{G}'$ resulting from an application of $\text{op}$ on $\mathcal{G}$ also fulfills the requirement. Two common operators are the merge and split operators.

1) split: divides the nonterminal $A_i \in \Omega_{\text{split}}$ into two new nonterminals $A_j, A_k$. The productions $R_{A_j}$ are separated randomly into two corresponding, disjoint sets $R_{A_j}$ and $R_{A_k}$, where none of the two resulting sets is empty. Each occurrence of $A_i$ is randomly replaced by either $A_j$ or $A_k$, where both $A_j$ and $A_k$ have to be selected at least once. The domain $\Omega_{\text{split}}$ contains all nonterminals with at least two productions. Furthermore, every nonterminal in $\Omega_{\text{split}}$ has to occur at least twice across all productions, including its own.

2) merge: combines two nonterminals $(A_j, A_k) \in \Omega_{\text{merge}}$ into a new nonterminal $A_i$. Correspondingly the productions of $A_i$ are defined as the union $R_{A_j} = R_{A_j} \cup R_{A_k}$. Every occurrence of $A_j$ and $A_k$ is replaced by $A_i$. If $A_j$ and $A_k$ contain production that begin or end in very different MP state spaces a merging would endanger the continuity requirement. We avoid this problem by restricting the domain $\Omega_{\text{merge}}$. The domain $\Omega_{\text{merge}}$ contains only pairs of nonterminals $(A_j, A_k)$, where all productions $R_{A_j} \cup R_{A_k}$ begin and end around a similar MP state space.

The split and merge operators negate each other and are capable of generalizing exiting hierarchies in grammars, however they lack the important ability to create new hierarchies. Therefore, we additionally utilize the chunk operator [12] and define the new insert operator that negates the effects of chunk.

3) chunk: creates a new nonterminal $A$ with productions $R_A = \{r\}$ for $r \in (\mathcal{A} \cup \mathcal{V})^+ \wedge r \in \Omega_{\text{chunk}}$. Every occurrence of the sequence $r$ in and production in $\mathcal{R}$ is replaced by $A$. The domain $\Omega_{\text{chunk}}$ contains all possible subsequences of all productions in $\mathcal{R}$.

4) insert: selects a nonterminal $A \in \Omega_{\text{insert}}$ and replaces each occurrence of $A$ with its production $r \in R_A$. The domain $\Omega_{\text{insert}}$ contains all nonterminals with exactly one production.

Given these four operators, we define the set of all possible operators as $\mathcal{O} = \{\text{merge}, \text{split}, \text{chunk}, \text{insert}\}$. Furthermore, the operators in $\mathcal{O}$ are not exchangeable i.e., if a grammar $\mathcal{G}'$ was created by applying the operator $\text{op}$ on grammar $\mathcal{G}$, there exists no operator in $\mathcal{O} \setminus \{\text{op}\}$ that is able to produce $\mathcal{G}'$ from $\mathcal{G}$.

C. Finding $\mathcal{G}^*$

Similarly to [13] we search for the optimal grammar $\mathcal{G}^* = \arg\max_\mathcal{G} p(\mathcal{G}|\mathcal{D})$ using an Markov chain Monte Carlo optimization. However, Talton et al. [13] already expected hierarchical inputs, restricting the grammar search to a reorganization of already existing productions by applying solely the merge and split operators. Given that our inputs are flat sequences, that is, pure sequences without hierarchy, of observed primitive samples, we additionally apply the chunk operator, that is capable of creating hierarchies [12].

The insert operator ensures the irreducibility of the Markov chain. Analogously to [13], we apply the Metropolis Hastings algorithm. However, since [13] solely uses the split and merge operator, the paper directly defines the proposal distributions $q(\mathcal{G}'|\mathcal{G})$ as the probability of an split or an merge. In this work we define the proposal distribution as a mixture over the four operators $\mathcal{O} = \{\text{merge}, \text{split}, \text{chunk}, \text{insert}\}$.

$$
q(\mathcal{G}', \text{op}) = \sum_{\text{op} \in \mathcal{O}} p(\text{op}|\mathcal{G}, \eta_{\text{op}}) q_{\text{op}}(\mathcal{G}'|\mathcal{G}, \text{op})
$$

with mixture components $q_{\text{op}}(\mathcal{G}'|\mathcal{G}, \text{op})$. The mixture probability is defined as

$$
p(\text{op}|\mathcal{G}, \eta_{\text{op}}) = \frac{\eta_{\text{op}} (1 - \delta_{|\Omega_{\text{op}}|})}{\sum_{\text{op} \in \mathcal{O}} \eta_{\text{op}} (1 - \delta_{|\Omega_{\text{op}}|})}
$$

where $\eta_{\text{op}} \in \mathcal{R}$ is a weighting for the operator $\text{op}$, $\delta_{|\Omega_{\text{op}}|}$ denotes the Kronecker delta over the size of the domain $\Omega_{\text{op}}$ for operator $\text{op}$. Given that the operators in $\mathcal{O}$ are exchangeable, a mixture component $q_{\text{op}}(\mathcal{G}'|\mathcal{G}, \text{op})$ should not contribute any probability mass if $\text{op} \neq \text{op}'$. This restriction is achieved by the Kronecker delta $\delta_{\text{op}', \text{op}}$ in the following mixture components.

1) $q_{\text{split}}(\mathcal{G}'|\mathcal{G}, \text{op}')$: Given that the split operator was applied to produce $\mathcal{G}'$ from $\mathcal{G}$, there exist $A_i \in \mathcal{V}$ and $A_j, A_k \in \mathcal{V}$. The chance of randomly selecting $A_i \in \Omega_{\text{split}}$ is $1/|\Omega_{\text{split}}|$. Additionally every production $r \in R_{A_i}$ was randomly assigned to either $R_{A_j}$ or $R_{A_k}$, while each of those two sets had to be selected at least once, resulting in the hypergeometric probability $H_{|R_{A_i}|} = H_{|R_{A_j}|} |2(|R_{A_j}| - 1), |R_{A_i}| - 1, |R_{A_j}| + |R_{A_k}||$. Finally, the $N_{A_i}$ occurrences of $A_i$ across all productions in $\mathcal{R}$ have been replaced by $N_{A_j}$ and $N_{A_k}$ occurrences of $A_j$ and $A_k$ in $\mathcal{R}'$, contributing yet another hypergeometric probability $H_{N_{A_j}} = H_{N_{A_k}} |2(N_{A_j} - 1), N_{A_j} - 1, N_{A_i} + N_{A_k}|$. The overall probability of $\mathcal{G}'$ being produced from $\mathcal{G}$ by using a split operator is given as:

$$
q_{\text{split}}(\mathcal{G}'|\mathcal{G}, \text{op}') = \frac{\delta_{\text{op}', \text{split}}}{|\Omega_{\text{split}}|} H_{|R_{A_i}|} H_{N_{A_j}} H_{N_{A_k}}
$$

2) $q_{\text{merge}}(\mathcal{G}'|\mathcal{G}, \text{op})$: The only stochastic part in the merge operator is the decision which pair $(A_i, A_j) \in \Omega_{\text{op}}$ is selected, therefore the probability for merge is given as

$$
q_{\text{merge}}(\mathcal{G}'|\mathcal{G}, \text{op}) = \frac{\delta_{\text{op}', \text{merge}}}{|\Omega_{\text{merge}}|}
$$

3) $q_{\text{chunk}}(\mathcal{G}'|\mathcal{G}, \text{op})$: Given that the domain $\Omega_{\text{chunk}}$ already contains all possible subsequences of all productions in $\mathcal{R}$, the probability for choosing one sequence at random is

$$
q_{\text{chunk}}(\mathcal{G}'|\mathcal{G}, \text{op}) = \frac{\delta_{\text{op}', \text{chunk}}}{|\Omega_{\text{chunk}}|}
$$
4) \( q_{\text{insert}}(G' | G, \omega_p') \): The domain \( \Omega_{\text{insert}} \) is already restricted to nonterminals with a single production, therefore the probability of \( \text{insert} \) is simply

\[
q_{\text{insert}}(G' | G, \omega_p') = \frac{\delta_{\omega_p', \text{insert}}}{|\Omega_{\text{insert}}|} .
\]  

At every iteration of the Metropolis-Hasting algorithm a random new grammar is sampled from the proposal distribution \( G', \omega_p' \sim q(G', \omega_p' | G) \). This new grammar is then accepted with a probability of

\[
\text{acc} \left( G', \omega_p' | G \right) = \min \left( 1, \frac{p(G' | D)^{1/T} q(G', \omega_p' | G')}{p(G | D)^{1/T} q(G', \omega_p | G)} \right) ,
\]

where \( T \) denotes a decaying temperature and \( \overline{\omega_p} \) denotes the complementary operator to \( \omega_p \), i.e. \( \text{split} = \text{merge} \), \( \text{chunk} = \text{insert} \). If the new grammar was accepted it is set to the current grammar \( G \leftarrow G' \) and the next iteration begins. After a defined number of iterations, the grammar with the highest posterior is returned.

V. EXPERIMENTS

We evaluated the proposed approach on two real robot tasks. First, we induced a grammar producing turns of the tic-tac-toe game. Second, we learned a grammar that assists a human with the assembly of a simple toolbox. In both tasks the necessary primitives were encoded as Probabilistic Movement Primitives [1]. For each of the tasks we compare the posterior resulting from our proposed prior, Grammar Poisson, with the one resulting from three common structure prior choices, MDL, Poisson + MDL, Avg. Poisson. The MDL prior is simply defined as an exponential distribution with the MDL as its energy [13]. The the Poisson + MDL prior weights the description language for every production with the Poisson probability over the length of the production [20]. Finally the Avg. Poisson prior discards the MDL completely and is solely represented by a Poisson distribution over the average length of all productions [11]. A major difference of the Grammar Poisson prior to the other discussed priors is that we do not model the distribution over the grammar parameters as a Dirichlet distribution but rather use them as a weighting for the average production length.

A. Learning a Grammar for Tic Tac Toe Turns

In this task we learned a grammar that allows the robot to play tic tac toe against a human. Each produced sequence corresponds to one turn of the game, i.e. picking a stone, closing the hand, placing the stone on the field, opening the hand and returning back to the home position. The goal is not to learn the logic behind the game but rather the induction of an intuitive grammar producing valid turns. The segmentation of the demonstrations and, hence, the learning of the primitives was done beforehand via Probabilistic Segmentation [5]. The five resulting arm primitives are shown in
The grammar learning was initialized with 16 observations of four unique sequences, each consisting of five terminals. The initial grammar is shown in Figure 4a. We initialized our approach with a desired number of rule \( \eta_R = 5 \), the desired number of average productions per rule \( \eta_R = 2 \) and the desired average length of each production \( \eta_r = 3 \). The weights for each operator were set uniformly to \( \eta_{op} = 1 \), \( op \in \mathcal{O} \). The MCMC optimization was run for 400 steps and resulted in 324 accepted grammars, the corresponding normalized posteriors are shown in Figure 5a, and the grammar with the highest posterior, grammar index 171 is shown in Figure 4b. The induced grammar intuitively represents, that each produced sequence will move a near or a far stone to either the left or the right side of the playing field. Furthermore, after every closing of the hand there will be a later opening of the hand. A possible sequence produced by the grammar, including the corresponding parse tree is seen in Figure 4b. For simplicity the naming of the nonterminals was chosen manually after the grammar learning. An automated naming of the nonterminals corresponding to the semantics of the productions is outside of the scope of this paper and remains a part of future work. Figure 5b-d shows the normalized posteriors corresponding to the three common priors. The x-axis corresponds to the different grammars traversed during the MCMC optimization, i.e. the grammar \( G^i, \)) \( \sim q \left(G^i, \right)\) \( \sim G^{i-1} \) was sampled from the proposal distribution around \( G^{i-1} \) by applying \( \text{op}^i \). The spiky behaviour of the posteriors (b-d) is due to the uninformative Dirichlet prior for the grammar parameters and the exponential distribution over the MDL. Both of these factors can change significantly with a small change in the grammar, e.g. a merge creating a rule with many productions or a chunk reducing the length of a long production. Furthermore, it is noticeable that the likelihood of the grammar \( p \left( G^i | D \right) \) does not play significantly into the posteriors of (b-d). This behaviour, is explained by the fact that the likelihood as defined in Equation (3) is a probability mass function, whereas the three priors are products of probability density functions. Our proposed prior however, is by definition a probability mass function, averaging over multiple Poisson distributions. Our posterior takes the likelihood and, therefore, the observations much stronger into account.

### B. Learning a Grammar for a Simple Toolbox Assembly

This task shows the abstraction capabilities of our approach. The demonstrations were again segmented beforehand and resulted in the five arm primitives, shown in Figure 6 and four hand primitives, closing and opening the hand for both a board and a screw grasp. The set of demonstrations contained three different sequences, consisting of 40 terminals each. Every observation showed the grasping and handing over of four boards and four screws, either alternating between the board and the screw or starting with two boards and alternating subsequently. The approach was initialized with \( \eta_R = 9 \), \( \eta_R = 2 \), \( \eta_r = 2 \). The weights for the split and merge operators were set to 1 and the remaining two were set to 2. The MCMC optimization ran for 400 iterations and 303 grammars were accepted.
posterior for the accepted grammars are shown alongside the likelihood in Figure 7. The posteriors show similar behavior as in the previous task. Both the MDL and the Poisson + MDL have a maximum at 162, indicating that the corresponding grammar has the minimal description length of all accepted grammars. The Avg. Poisson prior has its maximum at 44 du to a average production length close to $\eta_r$.

However, the corresponding grammar contains 14 rules with one production each. The grammar with the maximum posterior according to the Grammar Poisson prior is given at index 160 and presented in Figure 8. The grammar abstracts a full turn from taking a board or screw until going back to the home position. This subsequence was not marked in any way and was detected as a consequence of the grammar learning. The sequence occurred multiple times during each observation. Abstracting it into a nonterminal will therefore simplify the grammar significantly. Furthermore, the grammar encodes that a grasping of a board or a screw through the closing of the hand has to be eventually followed by the corresponding opening of the hand. The alternation between handing over a board and a screw is represented in the two rules for SBS and BSB and the rules for ASSEMBLE_SB. The option of starting with two boards is encoded in ASSEMBLE_BB.

VI. CONCLUSION

In this work, we introduced probabilistic context free grammars as a mechanism to sequence movement primitives. The paper presents an approach to induce such grammar from flat sequences of movement primitive samples, i.e., no hierarchy in the observations, while taking advantage of a stochastic primitive representation. The new introduced grammar prior is defined over several coupled Poisson distributions, and eliminates the many complications that arise from both Dirichlet parameter priors and minimal description length based structure priors. In our method, the hyperparameters of the prior have a clear semantic interpretation, namely the number of productions for each nonterminal and the average length of each production. The optimal posterior is learned using a Markov chain Monte Carlo optimization where the proposal distribution is formulated as a mixture model over four operators while avoiding local solutions. The learned grammars are simple and intuitive as evaluated in several experiments on a real robot platform.
